Abstract: The final goal for treatment of congenital heart diseases (CHD) is to resume not only the normal heart structure but also physiology. The present study evaluates surgical results at molecular basis on the proteomic pattern in the pre- and post-operative period in tetralogy of Fallot (TOF) and ventricular septal defect (VSD) in order to find whether structure repair is associated with clinically important molecular changes in CHD. Differential protein analysis by using two-dimensional gel electrophoresis and mass spectrometry followed by ELISA validation was performed in the plasma samples of patients with TOF (n=82) or VSD (n=82) preoperatively, 6-month postoperatively, and in normal controls (n=82). A total of 473 protein spots in preoperative patients and 515 in postoperative patients were detected. Significantly ($P<0.01$) downregulated or upregulated proteins were detected. Validation of proteins in the new cohort of patients demonstrated that in VSD patients, postoperative complement component C3c ($P<0.05$) was partially and serum amyloid P-component ($P<0.05$) was completely recovered. In TOF patients, postoperative gelsolin ($P<0.05$) was partially recovered. In contrast, the elevated fibrinogen gamma chain level ($P<0.01$) in preoperative patients became normal postoperatively ($P=0.1$ vs. control). Thus, we have for the first time by using proteomic methods demonstrated that repair surgery for CHD not only corrects the structure malformation but also resumes the normality of certain altered proteins at molecular level. Identification of the recovered or unchanged proteins may facilitate the evaluation of the surgical results and the personalized management in postoperative period and long-term.

Keywords: Congenital heart disease, surgery, repair, tetralogy of fallot, ventricular septal defect

Introduction

The traditional way to evaluate the result of a therapeutic method is mainly from the patient's clinical symptoms and signs. With new technology developed, it may extend to more precise ways by detecting or evaluating the biological specimens (cell populations, proteins, metabolites, RNA, and DNA- including whole-genome sequencing) in the era of precision medicine [1]. Better biomarkers are needed to assist with disease detection and to help guide treatment, particularly for common acquired conditions without a strong genetic predisposition [2]. In view of this, to evaluate repair surgery for congenital heart diseases (CHD), in addition to the

traditional method, such as using echocardiography to detect whether the heart structure is normal after heart surgery, new technologies based on multi-omics may play a role.

CHD are the most common birth defects affecting nearly 1% of human live births and are the leading causes of death in infants in the last decades [3]. Ventricular septal defect (VSD) is one of the most prevalent types of CHD, occurring in 30-60% of all neonates with various kinds of CHD [4]. Tetralogy of Fallot (TOF), on the other hand, represents the most common type of cyanotic CHD. Surgical repair remains the major method of treatment although cathe-

Surgery changes plasma protein profiling in congenital heart disease

ter-based repair is now used in some simple CHD cases.

Genetic causes of CHD have been increasingly reported. Multiple mutations such as in GATA4, TBX5, NKK2-5, Homez, PLAGL1 genes were identified on the VSD patients [5-9]. Similarly, a number of loci of variations have been identified in TOF patients [10]. In addition to the genetic causes, the differentially expressed plasma proteins that may reflect pathogenesis during development of the disease are clinically important. We have recently reported such differential plasma proteins in both VSD and TOF patients in the pre-operative period [11, 12]. These studies revealed plasma protein changes in CHD that may indicate the possible mechanisms for the prolonged bleeding time in TOF patients, the susceptibility to pulmonary infections in patients with CHDs [11], and altered acute phase proteins in VSD patients [12]. Further, we also demonstrated the proteomics changes in CHD with complications such as pulmonary arterial hypertension [13] and other heart diseases [14-16].

The final goal for treatment of CHD is to resume not only the normal heart structure but also normal life. Corrective surgery may turn the structure malformation of the heart to normal but it is unknown whether such repair is associated with molecular changes towards normal. In order to explore the surgical results at molecular basis in individuals towards "Precision Medicine" in the postoperative rehabilitation and the long term outcome, the knowledge regarding basic molecular changes after surgery is of importance. We therefore designed the present study to compare the proteomic profiling in the pre- and post-operative period in patients with TOF and VSD in order to find whether structure repair is associated with clinically important molecular changes in CHD.

Materials and methods

From Aug 2011 to 2015, blood samples were taken from patients with TOF (n=82) and VSD (n=82) at TEDA International Cardiovascular Hospital, Tianjin, China. The blood samples from 82 children with same ethnic, gender, and age for body-checking or in the CHD-screening program that demonstrated normal heart and no other diseases were used as control. All control subjects were confirmed by clinical screen-

ing plus echocardiography that confirmed no cardiac diseases. The protocol was approved by the Ethics Committee of TEDA-International Cardiovascular Hospital, Tianjin, China and informed consent was obtained from their parents or guardians. The demographics of the CHD patients and controls are shown in **Table 1**. Blood were taken before operation (n=41) in TOF and VSD (n=41) patients. During postoperative follow-up at the outpatient clinic, usually 6 months or longer after operation, blood was also taken in patients with TOF (n=41) or VSD (n=41). Routine clinical assessment of the patients was performed. All patients underwent corrective surgery and the diagnosis was verified by preoperative echocardiography and corrective surgery. Other diagnostic procedures such as MRI or CT scan were also used to help the definitive diagnosis when appropriate. Other complex CHDs were excluded. The enrolled VSD phenotypes included perimembranous (68), subarterial infundibular (7), and infracristal or intracristal type (7).

Sample preparation

Blood samples were taken from patients before surgery and 6 months after surgery as described above. From each sample, 2 ml blood was allowed to clot at 4°C for at least 2 h and then centrifuged at 1500 g for 10 min to reach sediment of the clotted cells. Plasma was then collected, divided into aliquots, and stored frozen at -80°C until the analysis was carried out.

Grouping of the samples

There were totally two groups and 6 subgroups: Preoperative group: I: VSD (N=41). II: TOF (N=41). III: the control (N=56). Postoperative group: Ia: VSD (N=41). IIa: TOF (N=41). IIIa: the control (N=41).

These subgroups of samples were studied in either proteomics or ELISA validations.

Proteomic study

Plasma high-abundance protein depletion: For the proteomic study, the plasma samples from TOF patients (n=15), VSD patients (n=15), and healthy controls (n=30 in pre-operative and n=15 in post-operative, respectively) were collected in these periods. These samples were separately pooled in each group and processed

Surgery changes plasma protein profiling in congenital heart disease

Table 1. Demographics of study population

Stage	Groups	Number	Sex (M/F)	Age (years)
2-DE	VSD (preop)	15	8/7	3.4 ± 4.6
	TOF (preop)	15	8/7	2.2 ± 9.9
	Controls	30	16/14	4.5 ± 11.5
	VSD (postop)	15	8/7	1.3 ± 1.1
	TOF (postop)	15	8/7	2.2 ± 2.0
	Controls	15	8/7	2.6 ± 1.0

to deplete high abundance proteins (albumin, immunoglobulin [Ig] G) using the ProteoExtract™ Albumin/IgG Removal Kit (Calbiochem, La Jolla, CA, USA). Samples were processed according to the manufacturer's instructions. Use of pooled serum samples from multiple patients is a well-accepted approach to better detect the differential proteins between the patients and controls [17]. The pre-operative and post-operative samples had their own healthy controls.

Two-dimensional gel electrophoresis (2-DE): The first-dimensional gel separation was carried out with Ready Strip immobilized pH gradient (IPG) strips (Bio-Rad, CA, USA), following the manufacturers protocol. About 500 µg protein of plasma for gel was diluted to 170 µL with rehydration solution (5 M urea, 2 M thiourea, 2% for 3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonate, 100 mM dithiothreitol, 0.5% v/v pH 3-10 IPG buffer, 40 mM Tris base, 2% sulfobetaine 3-10, and trace bromophenol blue), and applied to immobilized 17 cm pH 3-10 nonlinear gradient strips by overnight rehydration at 50 V.

Isoelectric focusing (IEF) was performed with an Ettan IPGphor II apparatus (GE Healthcare, Waukesha, WI) as followed steps: 0-500 V (500 Vh), 500 V (2,500 Vh), 500-3,500 V (10,000 Vh), 3,500 V (50,000 Vh), and 3,500-500 V (8,000 Vh) for a total of 7.1 kWh. All IEF steps were done at 20°C. After the first-dimensional IEF, IPG gel strips were placed in an equilibra-

tion solution (6 M urea, 2% sodium dodecyl sulfate, 30% glycerol, 50 mM Tris-HCl, pH 8.8) containing 1% dithiothreitol for 10 minutes with shaking at 50 rpm on an orbital shaker. The gels were then transferred to the equilibration solution containing 2.5% iodoacetamide and shaken for another 10 minutes before placing on 12% polyacrylamide gel slab.

The 2-DE separation was performed by using Protean II electrophoresis equipment and Tris-glycine buffer (25 mM Tris, 192 mM glycine) containing 0.1% sodium dodecyl sulfate at a current setting of 5 mA/gel for the initial first hour, and 10 mA/gel thereafter. The second-dimensional sodium dodecyl sulfate-polyacrylamide gel electrophoresis was developed until the bromophenol blue dye marker had reached the bottom of the gel. This process was repeated 3 times in each group as previously reported [11, 12, 15].

Image analysis

After 2-DE separation, there were totally 18 gels to be stained including the 3 technical repeats for each subgroup of the samples (there were 6 subgroups as mentioned above). The gels were stained with Coomassie blue R-250 (Sigma, St Louis, MO, USA). Spot detection and quantification were done using PD Quest 2-DE analysis software (Bio-Rad, Hercules, CA). Spot intensity was quantified automatically by calculation of spot volume after normalization of the image by taking the ratio of intensity of one spot to the total spots, and expressed as a fractional intensity. Only those spots with significant change between the disease group (TOF or VSD) and control ($P < 0.01$ by unpaired t test) in expression intensity were selected for MS analysis.

Tryptic digestion

Protein spots were excised from the gel with the Ettan Spot Picker and destained with 25 mM ammonium bicarbonate, 50% acetonitrile. Gels were then dried completely by centrifugally oophilization. Each spot was digested overnight in trypsin for 16 hours at 37°C. The pep-

Surgery changes plasma protein profiling in congenital heart disease

tides were extracted 3 times with 50% acetonitrile, 0.1% trifluoroacetic acid, and dried completely by centrifugal lyophilization.

MALDI/TOF MS

Before the analysis, external calibration with angiotensin II and ACTH 18-39 was used. This procedure typically results in mass accuracies of 100 ppm or better. The peptide mixture (0.3 µl) was then mixed with α-cyano-4-hydroxycinnamic acid matrix (1:1, v/v) and analyzed on an ABI 4700 MALDI-TOF/TOF Plus mass spectrometer (Applied Biosystems, USA), operated in the delayed extraction and reflector mode. The laser wavelength was 337 nm, and the laser repetition rate was 3 Hz. The MALDI spectra were averaged over 200–400 laser shots.

MALDI/TOF MS data analysis and bioinformatics analysis

Data were integrated and processed by using GPS Explorer software (Version 2.4.1, Applied Biosystems, USA). The peak list generated by 4000 Series Explorer software (Version 2.0, USA) was analyzed using the MASCOT (Version 2.4.1, Matrix Science, London, UK) search engine, which searched the 202,522 entries in the protein databases of the National Center for Biotechnology Information (NCBI) non-redundant human database (downloaded on 11/05/2014). Protein identification was carried out by peptide mass finger-printing (PMF). Search parameters were set as follows: precursor tolerance: ± 0.1 Da; missed cleavages: 1; fixed modifications: carbamidomethyl; variable modifications: oxidation. Threshold score/expectation value for accepting individual spectra was set to ion score 10. The MASCOT score from the sample with ammonium phosphate was higher than that from the sample without ammonium phosphate, thus increasing the confidence in the correct identification of the proteins.

Gene Ontology (GO), Kyoto Encyclopedia of Genes and Genomes (KEGG) [18], and STRING were performed for downstream analysis. GO contains biological process, cellular component, and molecular function categories. Enrichment analyses of KEGG pathways were performed with same hypergeometric algorithm used in gene ontology enrichment analysis. The pathways were clustered into the fol-

lowing sub-categories: metabolism, genetic information processing, environmental information processing, cellular processes, organismal systems, and human diseases. In GO analysis, some previously reported preoperative proteomic study [11, 12] was incorporated for a complete view.

Enzyme-linked immunosorbent assay

Further validation of candidate proteins was performed by using human ELISA kits (CUSABIO BIOTECH, Life Sciences Advanced Technologies Inc., USA) to detect plasma levels in a new cohort of pre- and post-operative patients (VSD or TOF) and their own control (N=26 for each group). The methods followed the manufacturer's instructions. The identification of candidate proteins for further validation was based on 1) expressed differently between VSD or TOF patients and the control; 2) potential functional or pathological significance in CHD; and 3) more than 1 peptide was identified by LC-MS/MS.

Statistical analysis

SPSS 17.0 software (SPSS Inc., Chicago, IL) and GraphPad Prism 5 Demo software (GraphPad Software, San Diego, CA) were used for statistical analysis. GO, KEGG, and STRING analyses were performed by using multi-omics data analysis tool (omicsbean, <http://www.omicsbean.cn>). The spot intensity was compared by unpaired t test. One-way ANOVA was used for comparing the ELISA verification among three groups. Data were expressed as mean ± SD. P<0.05 was considered as significant.

Results

2-DE analysis, MALDI/TOF MS identification

In proteomic studies, a total of 473 protein spots in preoperative patients ([Table S1](#)) and 515 in postoperative patients ([Table S2](#)) were detected. Significantly (P<0.01 vs. control) downregulated (11 in preoperative and 15 in postoperative group) and upregulated (14 in preoperative and 7 in postoperative group) protein spots were detected.

All 25 protein spots of interest in preoperative patients and 22 in postoperative patients were trypsin-digested and MALDI-TOF MS was used for the identification of the protein spots. In pre-

Surgery changes plasma protein profiling in congenital heart disease

operative study, 20 protein spots and 10 corresponding proteins or polypeptides could be identified whereas 5 protein spots did not have PMF or did not have corresponding proteins in the MASCOT database. In postoperative study, 15 protein spots and 11 corresponding proteins or polypeptides could be identified (**Table 2**) whereas 7 protein spots did not have PMF or did not have corresponding proteins in the MASCOT database.

GO, KEGG, and STRING analysis of the differentially expressed proteins (DEPs)

GO enrichment and KEGG pathway analysis were performed for an overview of the function of all of the DEPs and the potential linkage among them. **Figure 1A** and **1B** display the amount of GO enrichment analyses (biological process, cellular component, and molecular function) and KEGG pathways based on the DEPs (**Figure 1C, 1D**). *P* value <0.05 represents the significant GO terms and pathways for the DEPs between the disease group compared to the control in homo sapiens from GO and KEGG database. The DEPs were most significantly involved in regulation of heterotypic cell-cell adhesion in biological process, blood microparticle in cellular component, and protein binding-bridging in molecular function in preoperative proteomics results (**Figure 1E**). However, the DEPs were most significantly involved in apoptotic cell clearance in biological process, blood microparticle in cellular component, and C5a anaphylatoxin chemotactic receptor binding in molecular function in postoperative results (**Figure 1F**). Further KEGG pathway enrichment and STRING analysis (**Figure 2**) revealed that these proteins were mainly involved in complement and coagulation cascades and staphylococcus aureus infection in pre- (**Figure 2A, 2C**) and post- (**Figure 2B, 2D**) operative patients respectively. In the analysis, the common pathway was complement and coagulation cascade that is closely related to the pathology of CHD.

Significantly altered protein expression in patients with TOF and VSD

The present study emphasizes the proteomic profile after surgery. **Table 2** shows the altered proteins in the postoperative period that were most significant and confirmed with mass spectrometry. In the post-operative proteomic study in TOF group, three up-regulated proteins or polypeptides (Alpha-1-antichymotrypsin, Alpha-

1-antitrypsin, Fibrinogen gamma chain) and five down-regulated proteins or polypeptides (ceruloplasmin, C4B, serotransferrin, inter-alpha-trypsin inhibitor, H-ficolin) were identified (**Table 2**). In the postoperative VSD group, three down-regulated proteins or polypeptides (macroglobulin alpha2, complement component C3c, fibrinogen beta chain) were identified (**Table 2**).

Figures 3 and **4** demonstrate the differentially expressed proteins that were most significant in the proteomic study in preoperative patients with VSD (**Figure 3A**) or TOF (**Figure 4A**) and in postoperative patients with repaired VSD (**Figure 3B**) or TOF (**Figure 4B**). In details, **Figure 3** shows the 5 protein spots that were identified in either pre- or post-operative patients with VSD in the proteomic analysis. These are ficolin-3, alpha-1-glycoprotein 2, haptoglobin, serum amyloid P-component, and complement component C3c. Similarly, **Figure 4** shows the 3 protein spots that were identified in either pre- or post-operative patients with TOF in the proteomic analysis. Those are ficolin-3, gelsolin, and fibrinogen gamma chain. All the proteins were identified by mass spectrometry and the maps are shown in the lower middle panel in **Figures 3** and **4**.

Validation of the altered plasma proteins by ELISA

Further validation of the chosen proteins (ficolin-3, gelsolin, alpha-1-acid glycoprotein 2, haptoglobin, serum amyloid P-component, fibrinogen gamma chain, and complement component C3c) was performed by ELISA in 78 new patients (**Table 3**). **Figure 5** shows the results of ELISA validation of the differential proteins in pre-operative and post-operative patients with VSD (A-E, n=26), TOF (F-H, n=26), and in normal controls (n=26).

Discussion

The present study for the first time demonstrates that repair surgery in CHD changes the protein profile and that some of the preoperatively-changed proteins may be altered towards normal level after surgery. This study shows that repair surgery for either complex cyanotic CHD such as TOF or simple CHD such as VSD may change the pathological process of the disease to resume normal physiology.

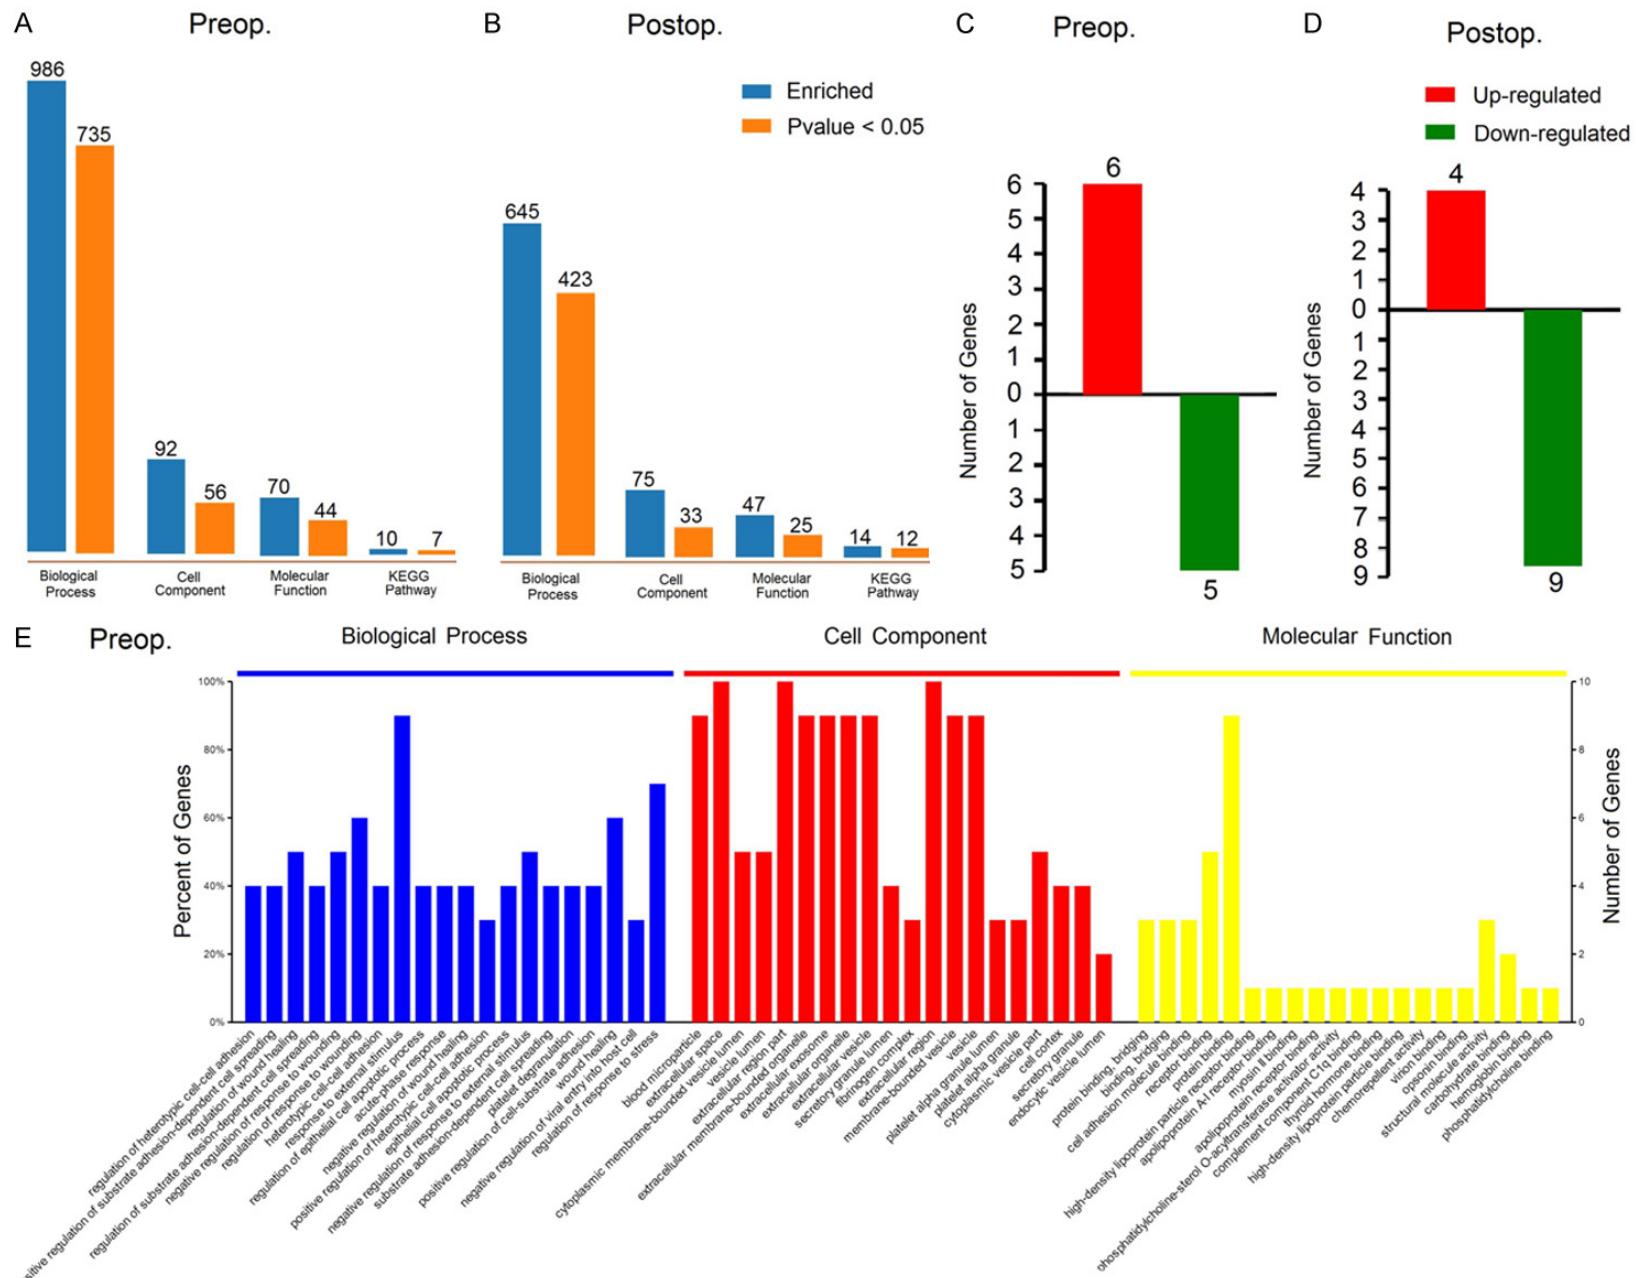

Surgery changes plasma protein profiling in congenital heart disease

Our study therefore provides important information regarding postoperative management after repair surgery in CHD.

We have previously demonstrated that in patients with CHD the protein profile is different from the normal subjects and this is true not only in complex CHD but also in simple CHD such as VSD [11, 12]. Moreover, as mentioned previously, the proteomic changes are also seen in CHD associated with complications such as pulmonary arterial hypertension [13] and other heart diseases [14, 15].

A clinically important question towards precision medicine is whether repair or corrective surgery may resume the physiological status towards normal in CHD, particularly in complex cyanotic CHD. This is an important issue in postoperative management of the patient as well as in evaluation of the patient to be a “normal” person for social activities in order to facilitate late education and personal life. The present study gives strong evidence that there are significant changes in the plasma protein profile after the repair surgery even as fast as 6 months postoperatively. The GO and KEGG analyses convincingly show that the protein profile and the top pathways have significant changes after surgery (**Figures 1, 2**). The validation of the proteins demonstrates that the proteins altered preoperatively, either up-regulated or down-regulated, changed towards normal after surgery. These results clearly show that surgery has changed the pathology of the disease and at least partially resumes the normal physiological level of these proteins. In VSD patients, these proteins include alpha-1-acid glycoprotein 2, serum amyloid P-component, and complement component C3c whereas in TOF patients, these proteins include fibrinogen gamma chain and gelsolin. It is obvious that the changed or “recovered” proteins are not limited to those validated proteins in the present study. Considering the function of these proteins, the clinical implications of these findings are significant.

Alpha-1-acid glycoprotein 2 (**Figure 5B**), also named orosomucoid 2 and serum amyloid P-component (**Figure 5D**) in VSD patients were down-regulated before operation and completely recovered after the repair surgery. Orosomucoid 2 is one of the major acute phase proteins in humans [12, 19] whereas haptoglo-

bin functions to bind free plasma hemoglobin [20] and plays a role in modulating many aspects of the acute phase response of the innate immune system [21]. Serum amyloid P-component is a member of the short pentraxin family. It was found that human amyloid P component may play a key role in the negative regulation of the innate immune response to DNA vaccines under physiological conditions [22]. The decrease of amyloid P component level in the plasma of VSD patients may facilitate innate immune response activation for stress response of organism against infection. Interestingly, the decrease of this protein in VSD patients resumed normal level after repair surgery for VSD.

We have previously shown that gelsolin was down-regulated in the plasma of patients with TOF (a typical cyanotic CHD) but was normal in VSD patients [11]. The finding in the present study that the content of gelsolin in plasma is partially recovered after surgery supports the notion that corrective surgery makes the coagulation system towards normal in TOF patients. As we previously discussed [11], gelsolin is required for rapid platelet activation [23, 24].

A similar result was found for complement component C3c in VSD patients. It was down-regulated before operation and partially recovered after the repair surgery. The complement system is an important mediator of natural and acquired immunity. It consists of approximately 30 proteins that can exhibit catalytic activity, function as regulators, or act as cellular surface receptors. These components normally circulate in inactive forms and are activated by the classical, alternative, or lectin pathways. Complement component C3c plays a central role in all three activation pathways [25].

We previously also found that ficolin-3 was down-regulated in the plasma of children with TOF and VSD [11]. Studies have demonstrated that children with CHD are more susceptible to infections [26] especially of the respiratory tract [22]. The finding of immuno-deficiency in patients with CHD in the present study may have important clinical implication in the management of infections and may be developed as a biomarker of susceptibility to infections in CHD patients. In the present study, in both diseases ficolin-3 was down-regulated and not recovered after surgery. There are two possibili-

Surgery changes plasma protein profiling in congenital heart disease

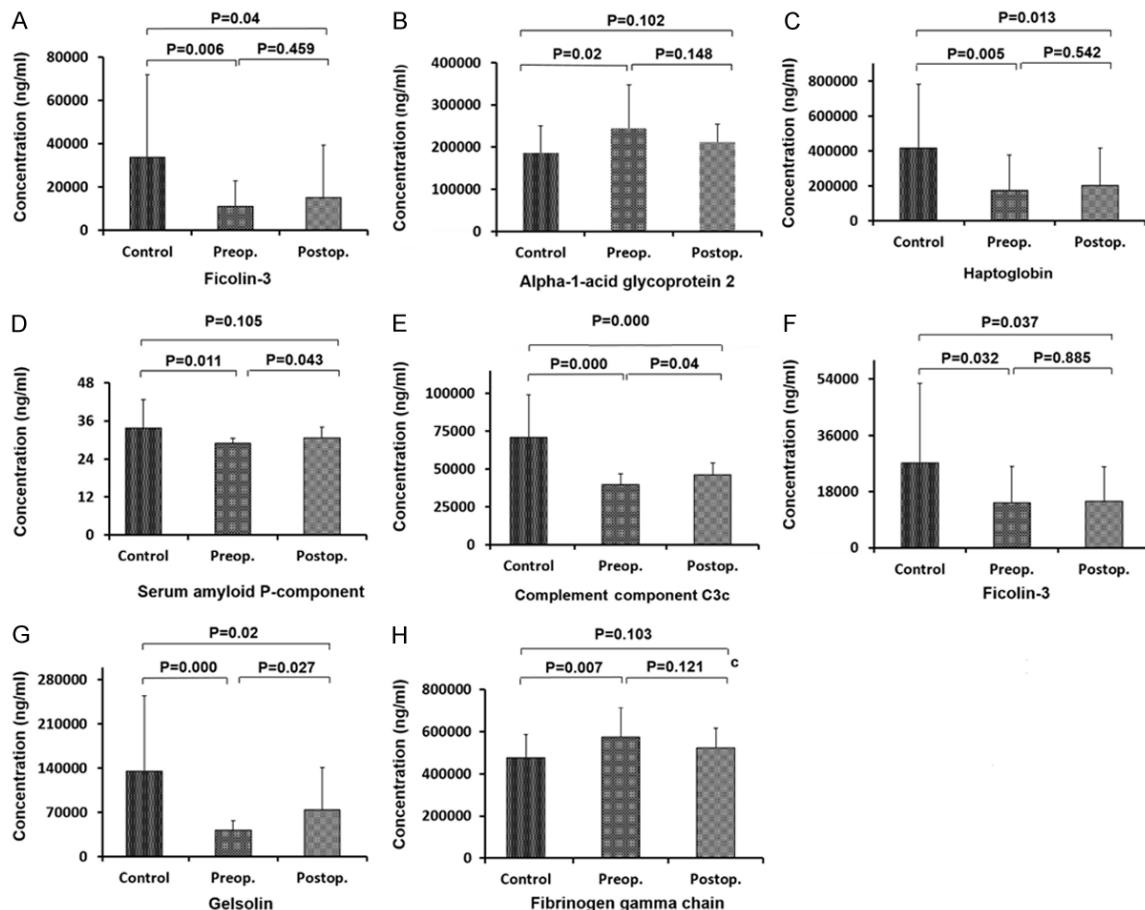

Figure 5. Validation of differentially expressed proteins in preoperative (Preop.) and postoperative (Postop.) patients with VSD (A-E, n=26), TOF (F-H, n=26), and normal controls (n=26). In VSD patients, postoperative complement component C3c ($P<0.05$) was partially and serum amyloid P-component ($P<0.05$) was completely recovered. In TOF patients, postoperative gelsolin ($P<0.05$) was partially recovered and the elevated fibrinogen gamma chain level ($P<0.01$) in preoperative patients became normal postoperatively ($P=0.1$).

ties to explain this result. Firstly, it suggests that the deficiency of ficolin-3 in CHD may be related to ficolin-3 gene deficiency and secondly, the deficiency of ficolin-3 in CHD may take longer than 6 months to recover. This result may suggest that careful management of the lung after repair surgery in CHD is necessary, at least in the early postoperative period.

Similarly, haptoglobin in VSD patients had no difference before and after surgery (Figure 5C). These results provide evidence that at least in the first 6 months after surgery, there are proteins that remain at abnormal levels.

It is interesting whether the findings from the present study are applicable in other CHDs. CHDs are complex diseases that have many different phenotypes. For example, some of the

left-to-right-shunt related CHDs are associated with pulmonary arterial hypertension that also has protein changes as we already demonstrated [13]. As to the mechanism of how each identified protein is affected by surgical repair is a more complicated issue and needs further studies. Nevertheless, the present study provides evidence for changes of the protein profiling after repair surgery in CHD. This translational significance needs all clinicians to be aware of.

In summary, CHD is associated with significant plasma protein changes that may well reflect the pathological nature of the disease. Repair surgery in CHD significantly changes the protein profiling. In particular, corrective surgery for TOF and VSD may change the abnormal pro-

tein profile towards normal. However, some of these altered proteins such as ficolin-3, haptoglobin, complement component C3c, and gelsolin may take longer time to reach the normal level after the repair surgery, or the deficiency may be related to the genetic basis in these patients.

Clinical perspectives

CHD are the most common birth defects affecting nearly 1% of human live births and are the leading causes of death in infants in the last decades. VSD is one of the most prevalent types of CHD, occurring in 30-60% of all neonates with various kinds of CHD, and TOF represents the most common type of cyanotic CHD. Surgical repair remains the major method of treatment.

This study reports that CHD is associated with significant plasma protein changes that may well reflect the pathological nature of the disease. Repair surgery in CHD significantly changes the protein profiling. In particular, corrective surgery for TOF and VSD may change the abnormal protein profile towards normal. However, some of these altered proteins such as ficolin-3, haptoglobin, complement component C3c, and gelsolin may take longer time to reach the normal level after the repair surgery, or the deficiency may be related to the genetic basis in these patients.

Our findings suggest that identification of the recovered or unchanged proteins postoperatively may facilitate the evaluation of the surgical results and the personalized management in the postoperative period and in the long-term in CHD patients.

In conclusion, by using proteomic methods we have demonstrated that repair surgery for CHD not only corrects the structure malformation but also resumes normal level of certain altered proteins. To identify the recovered or unchanged proteins postoperatively may facilitate the evaluation of the surgical results and the personalized management in the postoperative period and in the long-term in CHD patients.
